October 20, 2015

## Abstract

We investigate the effect of remittances from migrated family members on informal inter-household transfers - an issue that has received limited attention in the literature. Using rich panel data from urban Ethiopia, we show that receiving international remittances significantly increases the value of private domestic inter-household transfers, whereas receiving domestic remittances does not have any effect. We also show that the transfers sent respond to shocks to a great extent. Our results provide new evidence on the trickle-down effects of international remittances, effects important to consider when analyzing the impact of international remittances on household outcomes in recipient countries.

# 1 Introduction

In this paper, we use rich panel data spanning 15 years to investigate whether international remittances stimulate inter-household transfers in urban Ethiopia. Households in developing countries are vulnerable to risk and shocks and generally lack access to formal financial markets to insure themselves accordingly. Instead, households engage in a variety of informal strategies to mitigate risk and cope with shocks. For example, they may adjust their production choices and asset portfolios and engage in precautionary savings, gift-giving, and informal transfers (Paxson, 1992; Rosenzweig & Wolpin, 1993; Udry, 1995; Jacoby & Skoufias, 1997). International remittances are a type of informal transfer that has attracted increasing attention in the literature on transfers in developing countries in recent years. According to World Bank (2011), the value of international remittances to the developing world reached US\$350 billion in 2011, which is 50 percent more than the total official development assistance that these countries received from the developed world in the same year. The rapid increase in international remittances has sparked a large number of studies attempting to measure their impact on various household outcomes, including poverty, education, health, labor supply, and investment in recipient countries.<sup>1</sup>

Several previous studies (e.g., Adams et al., 2008 in Ghana; Lokshin et al., 2010 in Nepal; Taylor et. al, 2005 in Mexico; Yang & Martinez, 2006 in the Philippines; and Alem, 2015 in Ethiopia) have documented that remittances improve consumption by recipient households and hence reduce poverty. Remittances have also been shown to help households reduce consumption volatility (Combes & Ebeke, 2010), loosen liquidity constraints, and finance long-term human and physical capital investment (Taylor, 1999). A related strand of literature has also studied private inter-household transfer flows within countries (see, e.g., Cox, 1987; Cox, et al. 1998b, 2004). Studies from various developing countries indicate that a large share of the households are involved in private financial transfers and gift-giving with other households (e.g., Kazianga, 2006) and that households use these transfers as risk-sharing mechanisms (Fafchamps & Lund, 2003; Foster & Rosenzweig, 2001).

Although the impact of remittances on household outcomes and private transfer flows has been investigated separately in numerous previous studies, much less is known about the inter-linkages between receiving remittances and the sending of private inter-household transfers. Receiving remittances might enable a household to share more of its resources with other households, which could lead to trickle-down effects on non-migrant households that do not directly receive remittances. Investigating this issue is relevant because if households increase their transfers when they receive international remittances, then the effect of international remittances on welfare in recipient countries extends beyond the direct recipient households. This paper uses five rounds of rich panel data spanning 15 years from urban Ethiopia to investigate whether international and domestic remittances stimulate private inter-household transfers.

Urban Ethiopia is a valuable setting for studying the role of international remittances in stimulating inter-household transfers. The value of international remittances received by the country

---

<sup>1</sup>See Adams (2011) for an extensive survey of the recent literature on the household-level impact of international remittances in developing countries. Three earlier literature reviews have been undertaken by Lopez et al. (2005), Ruizz and Vargas-Silva (2009), and the Social Science Research Council (2009).

has increased rapidly in the last decade, and it has been shown that they play an important role in reducing households' poverty (Alem, 2015) and in improving subjective well-being among both urban and rural households (Alem & Köhlin, 2013; Andersson, 2012). In recent years, Ethiopia has also experienced rapid economic growth and double-digit inflation. The high inflation has affected the welfare of the urban population negatively, and informal transfers have become an important coping mechanism (Alem & Söderbom, 2012). In this context, analysis of the potential links between remittances and private transfers using robust panel data models on relatively long panel data provides an important opportunity to explore the additional channels through which remittances can affect household outcomes in migrant source countries.

We provide regression-based evidence that international remittances stimulate private inter-household transfers, while domestic remittances do not. We estimate alternative panel data models controlling for household fixed effects (time-invariant unobserved heterogeneity) to disentangle the effect of remittances on households' transfer behavior. Our results show that a one percent increase in the value of remittances received from abroad results in a 0.07 percent increase in transfers to other households. This finding provides some evidence on the trickle-down welfare effects of international remittances on households in recipient countries. However, we do not find a statistically significant impact of domestic remittances on inter-household transfers.

The rest of the paper is structured as follows. Section 2 discusses related literature and presents the Ethiopian context. Section 3 describes the panel data, and Section 4 outlines the empirical models used in the analysis. Section 5 presents the main empirical results from alternative linear panel data models, and Section 6 concludes the paper.

## 2 Related Literature

### 2.1 Private Inter-household Transfers

Private inter-household transfers are likely to be the main source of loans and transfers in developing countries, where there are limited public welfare programs and imperfect formal financial markets. Households form economic ties with each other and engage in income transfers, gift exchange, and other transactions to smooth consumption. In a seminal paper, Townsend (1994) shows how households in a village create informal arrangements to mitigate risk. Empirical evidence shows that inter-household transfers, remittances, and gifts are used for consumption-smoothing purposes in rural areas (Lucas & Stark, 1985; Rosenzweig, 1988). Similarly, Fafchamps and Lund (2003) show that households in rural Philippines rely on gift-giving and zero-interest informal credits as risk-sharing mechanisms within networks of friends and relatives. Although most studies on private inter-household transfers have focused on rural households, there is some evidence that such transfers also play an important role in risk sharing in urban areas of developing countries (e.g., Cox & Jimenez, 1998a; Kanzianga, 2006; Alvi & Dendir, 2009).

Apart from acting as important risk-sharing mechanisms, private inter-household transfers can potentially affect household welfare by redistributing the income gains from remittances sent from abroad. Most studies investigating the impact of remittances on households assume that the benefits are limited to the recipient households. The two exceptions to this observation are Yang

and Martinez (2006) and Beyene (2012). Yang and Martinez (2006) provide empirical evidence from the Philippines that remittances also affect non-recipient households. Their results show that an increase in remittances due to an exchange rate shock led to a decrease in poverty not only for migrant households but also for non-migrant households. They also show that an increase in the amount of remittances received from abroad increased the gift receipts by non-migrant households, suggesting that transfers between migrant and non-migrant households could at least partly explain the poverty reductions among non-migrant households in the Philippines. Beyene (2012) used a simple insurance model and the 2004 wave of the panel data we use in the present paper and documented, controlling for total household income and other covariates, that remittances have a positive impact on the amount of transfers sent to other households in urban Ethiopia.

How the sending of inter-household transfers responds to remittances received ultimately depends on the motives for sending transfers. Although determining the underlying transfer motives goes beyond the scope of this paper, theories of why households send transfers can give some guidance on how the receiving of remittances affects the sending of inter-household transfers. Three main models explaining the sending of private inter-household transfers are discussed and tested in the literature: *the altruistic model*, where the donor is driven by a concern about the well-being of the recipient and transfers depend on the financial situation of the donor and the recipient (Becker, 1974); *the exchange motive model*, where transfers are driven by reciprocity (Cox, 1987; Foster & Rosenzweig, 2001); and finally *the mutual insurance model*, where the donor enters into mutual agreements and uses transfers to smooth consumption (Townsend, 1994).<sup>2</sup>

Previous empirical studies on the motives driving inter-household transfers have typically been carried out by exploring how these transfers vary with the income of the recipient.<sup>3</sup> The studies are often motivated by crowding out concerns, i.e., if public transfers are followed by compensatory reductions in private transfers, the effect of the public transfer programs might ultimately be neutralized. Controlling for all other relevant household variables, the present study will take the income (or more precisely the remittance income) of the donor into account to shed light on how different motives could imply different predictions regarding the relationship between remittances and inter-household transfers. If altruism is the dominant motive, and the donor is concerned about the well-being of the recipient, an increase in remittances will lead to an increase in the sending of inter-household transfers. The same prediction holds for the exchange motive: an increase in remittances received enables the donor to send more transfers to benefit from more services in the future from transfer recipients. However, the predictions are more ambiguous if the decision to send inter-household transfers is based on insurance motives. Dercon (2005) argues that households may have incentives to leave a risk-sharing arrangement if they feel that staying in the arrangement is no longer in their interest. This could for example occur when a household experiences a positive income shock and prefers to make private investments rather than use the money to support others, or when the household begins to access to a new source of risk reduction or protection.

---

<sup>2</sup>In addition to these three motives, Mitrut and Nordblom (2010) also find social norms to be an important determinant of gift-giving in Romania.

<sup>3</sup>One exception is Clément (2008), who also develops predictions for how inter-household transfers vary with the income of the donor.

Consistent with Dercon's (2005) reasoning, households that receive remittances, and remittances from abroad in particular, might be less willing to engage in informal insurance arrangements if they feel that the income source in the form of remittances offers enough protection against adverse shocks. Hence, the effect of remittances on inter-household transfers is not clear a priori. Transfer motives may also affect how transfer patterns respond to an adverse shock. If the motives are altruistic, an adverse shock that affects the income of the household may lead to a decrease in the transfers sent. However, if other motives are at play, such as mutual insurance, the shock may not automatically translate into a decrease in inter-household transfers sent. The panel data we use in this paper, which spans the period when urban households in Ethiopia were severely affected by the 2008 food price inflation, enables us to shed lights on the transfer motives of remittance-receiving households.

## 2.2 The Ethiopian Context

Ethiopia makes an interesting case study to investigate the links between remittances and inter-household transfers. International remittance flows to the country have increased rapidly over the past decade. Alvi and Dendir (2009) show that households in urban areas in Ethiopia use transfers (including remittances, inter-household transfers, and gifts) as insurance against risks. They show that about one-third of these households are involved in transfer activities and that gifts and transfers respond positively to measures of vulnerability such as unemployment and illness of household heads.

The historic migration patterns in Ethiopia have been shaped by a mix of economic, political, and environmental factors. A noticeable international out-migration took place after the 1974 revolution and the political upheavals and instability that followed. The migrants were predominantly young and educated people from the urban elite. Later, the wish to migrate spread to other parts of the urban population, and in the 1980s the Middle East attracted migrants from both rural and urban areas (Aredo, 2005). The migration to the Middle East has since then expanded, especially among women, and is today one of the largest migration flows from Ethiopia (Fransen & Kuschminder, 2009; Kebede, 2002). Following the increase in the number of Ethiopian migrants abroad, international remittances to the country have increased substantially in recent years. According to World Bank estimates, the total value of the remittances has increased almost threefold in only a few years: from USD 46 million in 2003 to USD 387 million in 2010. The National Bank of Ethiopia reports even higher numbers: 661 million USD in 2009-2010, as cited in Geda and Irving (2011). The discrepancy is likely due to the difficulty in estimating remittances sent through informal channels. The rapid increase in the amount of international remittances documented by the World Bank and the National Bank of Ethiopia is consistent with the findings by Alem (2015), who shows a 142 percent increase in the number of urban households that received international remittances 2004-2009.

In Ethiopia, domestic migration flows are larger than the international migration flows (Fransen & Kuchminder, 2009). However, information about internal migration and remittances is relatively scarce. The 2008 Ethiopian Urban Migration Survey (World Bank, 2010), conducted among a representative sample of 1,115 households in Addis Ababa, shows that although a large share

of the internal migrants (more than 75 percent) stay in touch with their family and relatives in their area of origin, only 13 percent of the migrants send remittances back to their family. Slightly higher remittance rates were found by de Brauw et al. (2011) among migrants in a matched sample of rural households and domestic migrants. About one-third of the migrants in their sample sent remittances, which is a relatively low share compared with some of the large migration countries such as the Philippines and China. However, the figure is quite similar to other African contexts such as South Africa and the Kayes area of West Africa.<sup>4</sup> Migrants without skilled employment were less likely to send remittances, suggesting that internal remittances are low for reasons related to economic status.

The recent period when Ethiopia experienced a rapid increase in remittances (especially international remittances) was also characterized by rapid inflation. In July 2008, commodity prices were on average 52 percent higher than 12 months earlier, exhibiting the highest rate of inflation in Ethiopian history. The general inflation the country experienced in that period was mainly driven by food prices rising on average 92 percent in the 12-months period (Central Statistics Agency, 2008, 2009). Urban Ethiopian households were severely affected by the food price inflation and about 87 percent of them reported it to be the most influential shock during that period (Alem & Söderbom, 2012; Headey et al., 2012). Households had to cope with the shock by for example cutting back on quantities served per meal and receiving assistance from relatives and friends. One objective of the present paper is therefore to investigate how the links between remittances and inter-household transfers may be affected by an adverse shock.

### 3 Empirical Approach

Our main aim is to explore the effects of remittances on inter-household transfers in urban Ethiopia, and to shed light on whether the transfer behavior responds to the occurrence of shocks. Thus, our main outcome variable of interest is the real value of money transferred out by households. We specify a linear transfer equation for panel data as follows:

$$F_{it} = \beta_1 I_{it} + \beta_2 D_{it} + \beta_3 X_{it} + C_i + C_v + C_t + U_{it} \quad (1)$$

where subscript  $i$  denotes household,  $v$  city, and  $t$  year.  $F_{it}$  is the real values of transfers sent out by household  $i$  at time  $t$ .  $I_{it}$  corresponds to the real value of international remittances received by household  $i$  at time  $t$ , and  $D_{it}$  represents the real value of internal (domestic) remittances received. In addition to these core variables, we include a set of household head and other household-level variables as controls,  $X$ , that determine the amount of transfer sent by households.  $C_i$  corresponds to the household fixed effect (unobserved heterogeneity),  $C_v$ , to the city fixed effect, and  $C_t$ , to the year fixed effect.

The other explanatory variables captured in  $X_{it}$  include characteristics of the household head (age, gender, labor market status, and education); real monthly consumption expenditures per adult equivalent units, a proxy measure of economic status; and occupational and demographic characteristics of other household members. Our consumption measure was constructed as the

---

<sup>4</sup>See de Brauw et al. (2011) for further details.

sum of food and non-food expenditure. The consumption expenditure aggregated at the household level has been adjusted for spatial and temporal price differences using carefully constructed price indices from the survey. In order to take economies of scale and differences in needs into account we computed consumption expenditure in adult equivalent units.<sup>5</sup>

Previous research has also suggested that there might be different underlying motives for private transfers depending on the standard of living of the sender household (Cox et al. 2004; Kazianga, 2006; Clément, 2008), i.e., the transfer response to remittances might depend on how well off the household is. We investigate this by allowing the effect of receiving remittances to vary with the education level of household heads, which captures the ability of households to generate income. In doing so, we create interaction terms between international remittances and education level of household heads and control for them in the empirical model specified above.

The fundamental problem encountered in estimating equation (1) using OLS is the possible correlation between  $X_{it}$  and  $C_i$ . If such a correlation does not exist, i.e., if  $E(X_{it}C_i) = 0$ , OLS would be consistent. However, if there is no correlation, the random effects model, which works in a Generalized Least Square (GLS) framework would yield a more efficient estimator of the  $\beta$  parameters. Very often in applied research, however, the assumption that  $E(X_{it}C_i) = 0$  is strong, even though the  $U_{it}$ s are independently distributed. There are several cases under which some of the explanatory variables including remittances (our core variables) would be correlated with the unobserved heterogeneity term  $C_i$ . For example, in the context of the transfer equation formulated above, sending a migrant abroad and receiving remittances would most likely be correlated with unobserved household characteristics.  $C_i$  could also be correlated with many other explanatory variables, such as educational achievement, as some household members may have a higher level of motivation to pursue higher level education.

The most credible way of estimating the  $\beta$  parameters by disentangling the unobserved heterogeneity term is application of the fixed effects model, which works through OLS estimation of the within transformation of the basic equation stated in (1). One limitation of this estimator, however, is that the coefficients of time-invariant observable characteristics cannot be identified, as they are dropped through the within transformation. If the interest is focused on the time-varying variables of the model, the fixed effects estimator provides the most robust parameter estimates (Wooldridge, 2010). If the random effects model is not supported by the test<sup>6</sup> and there is interest in the  $\beta$ s of the time-invariant variables, the reasonable model to consider is the Hausman-Taylor two-stage model.<sup>7</sup> In order to investigate the magnitude of the relationship between remittances and household transfer behavior, we estimate different panel data models.

<sup>5</sup>See Alem and Söderbom (2012) for details on construction of the consumption variable.

<sup>6</sup>The standard test for this is the Hausman test, which tests for the null hypothesis that  $E(X_{it}C_i) = 0$  (Wooldridge, 2010).

<sup>7</sup>In this model, the explanatory variables would be categorized into four variables: time-variant and uncorrelated with  $C_i$ , time-variant and correlated with  $C_i$ , time-invariant and uncorrelated with  $C_i$ , and time-invariant and correlated with  $C_i$ . The model is then estimated using the exogenous variables within the model as instruments in a two-stage framework. See Wooldridge (2010) for details.

## 4 Data and Descriptive Statistics

Our empirical analysis is based on five rounds of the Ethiopian Urban Socio-economic Survey (EUSS), a panel dataset collected in 1994, 1997, 2000, 2004, and 2009. The first four waves of the data were collected by the Department of Economics at Addis Ababa University in collaboration with the University of Gothenburg. A stratified sampling technique was used to form 1,500 households in total, which represent the Ethiopian urban population. The sample households were allocated to seven representative cities - the capital Addis Ababa, Awassa, Bahir Dar, Dessie, Dire Dawa, Jimma, and Mekelle - based on the proportion of their population. Once the sample size for each city had been set, it was distributed over all weredas (districts) in each urban center. Using the resident registry available at the urban administrative units, households were then selected randomly from half of the kebeles (the lowest administrative units) in each wereda.

The most recent survey, fielded by the corresponding author in late 2008 and early 2009, covered 709 households in Addis Ababa, Awassa, Dessie, and Mekelle.<sup>8</sup> All panel households were surveyed in three of the cities, but not in Addis Ababa, which constituted about 60 percent of the original sample. About 350 of the original households in Addis Ababa were selected following the sampling procedure outlined above. Out of the 709 households surveyed in the 2009 round, 128 were new households chosen randomly and incorporated into the sample. These new households were surveyed in order to investigate whether the panel households initially selected in 1994 had become atypical and not representative of the Ethiopian urban population. Given for instance the rapid urbanization and structural change in Ethiopia over the past decade, the newly formed households might be systematically different in their characteristics from the panel households, affecting the representativeness of the data. However, Alem and Söderbom (2012) investigate this and find no significant difference in welfare between the panel and the newly incorporated households.

Given that the sample size had to be reduced substantially in the most recent wave, it is reasonable to be concerned about bias in the estimation results as a result of attrition. Alem (2015) and Alem et al. (2014), who used the panel dataset for related research, attempted to investigate attrition bias using attrition probits (Fitzgerald et al., 1998) and a Beckett, Gould, Lillard, and Welch (BGLW) test (Beckett et al., 1988). Attrition probits represent estimates of binary-choice models for the determinants of attrition in later periods as a function of base year characteristics. The BGLW test, on the other hand, involves investigating the effect of future attrition on the initial period's outcome variable. Based on these tests, the authors conclude that it is unlikely that attrition in the sample would bias the results for the remaining sample.

The dataset contains rich information at the individual and household levels related to household demographics, education, health, labor market status, and household consumption. Information on domestic and international remittances received and transfers sent by households in the 12 months prior to the survey was also included.<sup>9</sup> The transfers recorded in the survey can be

---

<sup>8</sup>Other cities were not covered due to resource constraints.

<sup>9</sup>It is possible to be concerned about the possibility that some of the international remittances might have been transferred through the household for other households not covered in our survey. However, the EUSS survey questions were explicit and asked about remittances received by household members only, who transferred them

divided into three main categories: remittances from abroad, remittances from domestic sources, and gifts received.<sup>10</sup> In this study we focus on the first two transfer flows. The survey recorded values of both cash and in-kind transfers. In the case of in-kind remittances, the households were asked to estimate the monetary value in the local currency, birr. The variable for transfers sent by a household is derived from a survey question about the total value of transfers given by the household in the 12 months prior to the survey. The question about private transfers given is hence not as detailed as the questions about transfers received.<sup>11</sup> There is no detailed information on the recipients' transfers and what the purpose of them was.

Table 1 provides summary statistics of household transfer flows for all households by year. All amounts are expressed in 1994 Ethiopian birr.<sup>12</sup> As can be seen, the proportion of households that receive international and internal remittances increased over time, with the largest increase occurring between the two last waves. In 2009, 27.2 percent of the households received international remittances and 25.9 percent received domestic remittances, to be compared with the shares in 2004 of 13.9 percent and 11.1 percent, respectively. The share of households sending inter-household transfers also increased substantially 2004-2009, from approximately 9 percent to almost 20 percent. This is the period when Ethiopia experienced rapid inflation. Thus, the rapid increase in the proportion of households receiving remittances and those sending inter-household transfers is not surprising, as households used these informal transfers to deal with the food price shock (Alem & Söderbom, 2012).

Table 1 about here

When looking at the amounts of transfer flows, the picture looks a bit different. Both real international and domestic remittances increased in the early years of the panel and decreased in the last year. The mean amounts of international remittances received in real terms were highest in 2004 and lowest in 2009. Domestic remittances also followed the same trend of increasing and then decreasing in the last round. Thus, it is evident that more households received remittances in later years, but the mean values received in real terms declined over time, especially in the case of international remittances. One potential explanation could be that during the food price shock in 2008, the need for remittances increased and migrants consequently sent remittances to more households than in previous years, reducing the real value of each remittance. Another explanation is related to the rapid inflation the country experienced between 2004 and 2009 which affected the price index used to adjust for spatial and temporal price differences. Remittances and consumption expenditures have been adjusted for spatial and temporal price differences using price indices constructed from the survey. Since prices increased more than three fold between 2004 and 2009, the nominal value of remittances in 2009 had to be deflated more proportionately than all other years. Indeed descriptive statistics from the data show that the mean value of international remittances received in nominal terms in 2009 was 621 birr being about 20 percent

---

and how they were spent.

<sup>10</sup>The survey also includes questions on public transfers, such as food aid and food-for-work. These transfers represent very small proportions of the transfers received by the households and are excluded from the analysis.

<sup>11</sup>As discussed by, e.g., Cox et al., (2004), asking much more detailed questions about transfers received than transfers sent could potentially lead to an underestimation of transfers sent.

<sup>12</sup>One US \$ was approximately five Ethiopian birr in 1994.

higher than the value in 2004 which was 516 birr.<sup>13</sup>

Unlike the proportion of households sending inter-household transfers, the mean value of inter-household transfers sent documents a cyclical trend. Compared to 1994, the mean value of inter-household transfers in real terms increased in 1997, declined in 2000, increased again in 2004 with another decline in 2009. The decrease in the last wave might reflect the more difficult times faced by urban households during the period of high food price inflation in 2008.

## 5 Regression Results

Table 2 presents panel data regression results for private transfer equations from different linear models for households in urban Ethiopia. To test for the robustness of the effect of remittances on inter-household transfers, we estimated the regression using four alternative specifications: pooled ordinary least square (OLS), random effects (RE), fixed effects (FE), and Hausman-Taylor (HT) estimators. The robust Hausman test rejects the random effects estimator (p-value of 0.000) and consequently we do not present and discuss the RE results. Estimation results from the other three models are presented in columns [1]-[3] of Table 2. The full set of variables used in the regressions are presented in Table A.1 in the appendix.

The regression results from all models indicate that international remittances increase inter-household transfers. According to the OLS results, a one percent increase in international remittances results in a 0.049 percent increase in transfers to other households. However, the panel data models that control for time-invariant unobserved factors reveal larger magnitudes. For example, the HT regression results show that a one percent increase in international remittances results in a 0.07 percent increase in transfers sent. This represents a 42 percent increase in the magnitude of the international remittances variable. The results therefore imply a strong need for controlling for unobserved household characteristics. This is consistent with the large literature on international migration that documents that households sending a migrant abroad and receiving remittances have distinct unobserved characteristics, that should be controlled in regressions (Lopez et al., 2005; Ruizz & Vargas-Silva, 2009; Adams, 2011). We do not however find a statistically significant impact of domestic remittances. The variable is weakly significant (at 10 percent) in the OLS regression but not in any of the panel data models and its magnitude (0.02) is substantially lower than that of international remittances.

Table 2 about here

As shown in the descriptive statistics presented in the previous section, the strong impact of international remittances on inter-household transfers is likely due to international remittances being larger and having increased substantially in recent years. The results provide evidence that receiving international remittances enables households to share more of their resources with other households, which leads to trickle-down effects on non-migrant households that do not directly receive international remittances. The increases in inter-household transfers in response to international remittances provide some support for the altruistic and insurance motives. About

---

<sup>13</sup>Another plausible reason may be that remittance senders living abroad themselves might have been affected by the global economic crisis during the 2007-2008 period.

82 percent of international remittances received by households were sent by their grown children, which suggests additional evidence for these motives.

Sending of inter-household transfers is also influenced by the economic status of the sending household as measured by the log value of real consumption expenditure per capita. OLS results show that a one percent increase in real consumption expenditure per capita increases transfers sent by 0.41 percent. However, about 25 percent of this impact is explained by unobserved household characteristics. This can be seen from the decline in the magnitude of the consumption variable to 0.31 in the HT model. The positive impact of consumption expenditure on inter-household transfers is consistent with the altruistic motive of sending transfers, i.e., sender households are concerned about the well-being of the recipient and hence increase the transfer amounts as their income increases.

We will now analyze how inter-household transfers sent are affected by observable household head characteristics. Regression results reported in Table 2 suggest that households headed by individuals with tertiary education and those headed by an employer or a self-employed worker transfer more than the reference groups (uneducated heads and out-of-the-labor force heads, respectively). OLS results show that compared with a household with an illiterate head, a household headed by an individual with tertiary education has a 72.4 percent higher probability of sending inter-household transfers. The dummy for tertiary education in fact represents the largest coefficient of all control variables included in the transfer equation. However, controlling for time-invariant household unobservables reduces the impact of tertiary education as well. According to the HT model, the impact of a household being headed by a person with tertiary education is 0.486, representing a 48.6 percent higher likelihood of sending out inter-household transfer compared with a household headed by an illiterate individual. Previous studies in urban Ethiopia (e.g., Alem & Söderbom, 2012; Alem et al., 2014; Alem, 2015; Gebremedhin, & Whelan, 2005) have documented that these types of households enjoy higher level of consumption and subjective well-being and are less likely to be in poverty. This most probably reflects the large return to tertiary education in the rapidly growing Ethiopian urban sector. The results also show that male-headed households are more likely than female-headed households to send inter-household transfers.

The present paper takes a comprehensive view of the household and considers the role of other household members in household decisions. We control for a broad set of other household members' occupational and demographic characteristics in our transfer equations. All three linear models presented in Table 2 suggest that not only household head characteristics but also other household members' occupational and demographic characteristics have a significant effect on the amount of transfers sent. Consistent with our discussion above, households with more members earning a living as a self-employed worker, a civil/public sector worker, or a private sector worker have a higher likelihood of sending inter-household transfers. This likely captures the role of other household members in household-level decisions and highlights the importance of controlling for them in addition to the commonly used household head characteristics.

Finally, the coefficients on the city and time dummies indicate a clear spatial and temporal variation in the amount of inter-household transfers sent by households in urban parts of Ethiopia. Compared with the reference group (households in Mekelle), households in the capital Addis have

a 21.2 percent lower probability of sending inter-household transfers. Addis is a more developed metropolitan city than Mekelle with better access to modern financial institutions. As a result, controlling for all other relevant variables, households may have a lower likelihood of engaging in transfer arrangements. The results also show that inter-household transfers increased significantly in the most recent wave, i.e., in 2009. This wave captured the country’s unprecedented food price shock, which led to a significant proportion of households engaging in inter-household transfers. The 2009 wave included a question on households’ strategies to cope with the food price shock. The responses to this question are consistent with this observation.<sup>14</sup> The data shows that approximately 22 percent of the households stated assistance from relatives or friends as their main coping mechanism to cope with the food price shock, making it second in importance only to cutting back on quantities served per meal.

### **Heterogenous Effects by Education**

Previous research has suggested that the motives for inter-household transfers for the sending household may vary with the standard of living of the household (Cox et al., 2004; Kazianga, 2006; Clément, 2008). It is therefore possible that the transfer response to remittances depends on how well off the household is. We investigate if receiving remittances has a differential impact on transfers sent out by allowing the effect of receiving remittances to vary with the education level of household heads, which captures the underlying ability of households to generate income. In doing so, we created interaction terms between the educational level of household heads and international remittances and ran all regression models.

The regression results with interaction terms for private transfer equations are presented in Table 3. The results provide interesting insights regarding the role of international remittances on inter-household transfers based on education level of household heads. The effect of international remittances on private transfers is lower for households headed by an individual with tertiary education. The magnitude of the interaction term between tertiary education and international remittances is -0.09 and -0.08 in the fixed effects and Hausman-Taylor models, respectively. This indicates that receiving international remittances has a lower effect on inter-household transfers if the household head has completed tertiary education. Households headed by an individual with tertiary education are relatively well off and often the head works in the formal sector. In view of this, they are likely to have access to modern financial institutions and hence are less likely to engage in inter-household transfers.

Table 3 about here

## **6 Conclusions**

Households in developing countries without access to formal financial institutions engage in a variety of informal strategies to deal with risk and shocks. International remittances are a type of

---

<sup>14</sup>As shown by Alem & Söderbom (2012), the most widespread and severe shock that the households faced was by far the food price shock: 94 percent of the households stated that they had experienced such a shock, and 87 percent identified the increase in food prices as the shock with the strongest impact on the household.

informal transfer that has attracted increasing attention in the literature on transfers in developing countries. This paper used five waves of panel data to investigate the role of remittances on inter-household transfer behavior - an aspect that has not received sufficient attention in previous studies. The availability of such a long panel dataset enabled us to control for confounding time-invariant unobserved household factors and explore the role of remittances on households' transfer behavior. We estimated alternative linear panel data models for transfer equations by households in urban Ethiopia.

Regression results show that receiving international remittances increases the value of transfers sent by recipient households. A one percent increase in international remittances results in a 0.07 increase in inter-household transfers sent. The magnitude of domestic remittances on the other hand is very low (0.02) and statistically insignificant, suggesting that it plays little role in stimulating inter-household transfers. The most plausible explanation for these results - suggested by the patterns in our data and the regression results - is that international remittances are larger in amount and have a positive impact on transfers sent, mainly through the altruistic and informal insurance motives. Most international remittances (about 82%) are transferred by children of household heads, providing additional evidence for these motives. We also documented that both remittances and private transfers increased substantially in the period when the country experienced a rapid food price shock. This provides strong evidence that informal transfers serve as an important mechanisms to cope with shocks.

We provided the first comprehensive evidence on the possible role of international remittances in stimulating inter-household transfers using panel data that tracks the same households for a long period in a developing country. If households transfer more when they receive more international remittances, the effect of international remittances on welfare in recipient countries extends beyond the direct recipient households. We document this trickle-down effect, and thus our results are relevant in that they shed light on the possible additional channels through which remittances can affect household outcomes in migrant source countries. Although our panel data is rich and the longest ever to be used in the context of our paper, we acknowledge the possible limitations of our study. Our data did not contain information on which countries the international remittances were transferred from and what the exact motives for inter-household transfers were. Future research with more detailed data on households' transfer motives and the characteristics of recipients of inter-household transfers could shed additional light on the topic explored.
